

Best mean-field for condensates

L.S. Cederbaum and A.I. Streltsov

Theoretische Chemie, Universität Heidelberg, D-69120 Heidelberg, Germany

Abstract

The Gross-Pitaevskii equation assumes that all (identical) bosons of a condensate reside in a single one-particle function. Here, we raise the question whether it always provides the best mean-field ansatz for condensates, leading to the lowest mean-field ground state energy. To this end, we derive a mean-field approach allowing for bosons to reside in several different one-particle functions. The number of bosons in each of these functions is a variational parameter minimizing the energy. The energy and one-particle functions at these optimal numbers can be determined directly. A numerical example is presented demonstrating that the mean-field energy of trapped bosons can be below that provided by the Gross-Pitaevskii equation. Implications are discussed.

Non-linear Schrödinger equations are widely used in many areas of physics and chemistry. In fact, the mean-field equation of any many-body system is a non-linear Schrödinger equation. Usually, however, one speaks of *the* non-linear Schrödinger equation if this equation takes on a particular form. This equation is used to describe many phenomena like solitons [1], optical pulses in fibres [2], Bose-condensed photons [3] and others. Motivated by famous experiments [4,5,6], extensive use of this equation has been made in recent years to describe dilute gas Bose-Einstein condensates [7]. In the context of such condensates this equation is also referred to as Gross-Pitaevskii (GP) equation [8,9].

The non-linear Schrödinger equation can be derived as the mean-field equation of a system of N identical bosons which interact via a δ -function potential $W(\vec{r}_1 - \vec{r}_2) = \lambda_0 \delta(\vec{r}_1 - \vec{r}_2)$, where $\vec{r}_i$ is the position of the i -th particle. It is equivalent to the GP equation if we identify the appearing non-linear parameter with the s-wave scattering length of the particles [7]. At zero temperature all bosons can occupy the same spatial one-particle function (orbital) if their mutual interaction is neglected. The mean-field description of the interacting

system is obtained by assuming the ground state wave function Ψ to be a product of identical spatial orbitals φ : $\Psi(\vec{r}_1, \vec{r}_2, \dots, \vec{r}_N) = \varphi(\vec{r}_1)\varphi(\vec{r}_2)\cdots\varphi(\vec{r}_N)$. The energy $E \equiv \langle \Psi | \hat{H} | \Psi \rangle$ defined as the expectation value of the widely used [7,10] Hamiltonian $\hat{H} = h + W$, reads

$$E_{GP} = N \left\{ \int \varphi^* h \varphi d\vec{r} + \frac{\lambda}{2} \int |\varphi|^4 d\vec{r} \right\}, \lambda = \lambda_0(N-1) \quad (1)$$

where $h(\vec{r}) = \hat{T} + \hat{V}(\vec{r})$ is the unperturbed one-particle Hamiltonian consisting of the kinetic operator $\hat{T}$ and the external potential $\hat{V}(\vec{r})$. By minimizing this energy one readily obtains the GP equation for the optimal orbital φ :

$$\{ h(\vec{r}) + \lambda |\varphi(\vec{r})|^2 \} \varphi(\vec{r}) = \mu_{GP} \varphi(\vec{r}) \quad (2)$$

Solution of this eigenvalue equation determines this φ and μ_{GP} which is called the chemical potential [7].

The GP equation and energy are very appealing and have been successful in explaining experimental observations. We raise the question, however, whether the GP approach always provides the best mean-field description of the system. We shall demonstrate below that *other* mean-fields may provide a lower energy than (1) does, at least in some cases. The general wave function of N non-interacting bosons is a product $\varphi_1(\vec{r}_1)\varphi_2(\vec{r}_2)\cdots\varphi_N(\vec{r}_N)$ of orbitals which can all be different. Since the bosons are identical, this product must, of course, be symmetrized and several bosons may occupy the same spatial orbital. We may put n_1 bosons in orbital φ_1 , n_2 in orbital φ_2 and so on. By definition the most general mean-field energy is $E = \langle \Psi | \hat{H} | \Psi \rangle$ where Ψ is the above symmetrized product. For transparency of presentation we confine ourselves in the following to two orbitals φ_1 and φ_2 with particle occupations n_1 and n_2 , respectively, where $n_1 + n_2 = N$. The extension to more orbitals is trivial. The energy now reads

$$E = n_1 h_{11} + n_2 h_{22} + \lambda_0 \frac{n_1(n_1-1)}{2} \int |\varphi_1|^4 d\vec{r} + \lambda_0 \frac{n_2(n_2-1)}{2} \int |\varphi_2|^4 d\vec{r} + 2\lambda_0 n_1 n_2 \int |\varphi_1|^2 |\varphi_2|^2 d\vec{r} \quad (3)$$

where $h_{ii} = \int \varphi_i^* h \varphi_i d\vec{r}$ is the usual one-particle energy. Minimizing this energy with respect to φ_1 and φ_2 under the constraints that they are orthogonal, $\langle \varphi_1 | \varphi_2 \rangle = 0$, and normalized to unity, $\langle \varphi_i | \varphi_i \rangle = 1$, we obtain the following equations

$$\{ h(\vec{r}) + \lambda_0(n_1-1)|\varphi_1(\vec{r})|^2 + 2\lambda_0 n_2 |\varphi_2(\vec{r})|^2 \} \varphi_1(\vec{r}) =$$

$$\begin{aligned}
&= \mu_{11} \varphi_1(\vec{r}) + \mu_{12} \varphi_2(\vec{r}) \\
\{ h(\vec{r}) + \lambda_0(n_2 - 1)|\varphi_2(\vec{r})|^2 + 2\lambda_0 n_1 |\varphi_1(\vec{r})|^2 \} \varphi_2(\vec{r}) &= \\
&= \mu_{22} \varphi_2(\vec{r}) + \mu_{21} \varphi_1(\vec{r})
\end{aligned} \tag{4}$$

for the optimal orbitals. These equations should not be confused with those for condensates made of two types of bosons. The μ_{ij} are the Lagrange parameters due to the above mentioned constraints. Of course, the energy E and the orbitals φ_1, φ_2 depend on the particle occupation n_1 . Consequently, we may treat n_1 as a variational parameter and search for its optimal value which minimizes the energy. We shall return to this central point below.

Here, we briefly make contact with the problem of fragmentation often discussed in the literature, see refs. [11,12] and references therein. A condensate is fragmented if its reduced one-body density matrix has two or more macroscopic eigenvalues. Until now no fragmentation has been found for confined condensates, i.e., for condensates in an external potential. Moreover, it has been shown that fragmentation cannot take place in a harmonic external potentials [13]. Our ansatz discussed above in eqs.(3,4) can describe fragmentation on the mean-field level. If the particle occupations n_1 and n_2 minimizing the energy are both macroscopic for large N , fragmentation takes place.

Let us analyze eqs.(3,4). Using eq.(1) it follows that the energy needed to remove a particle without changing the orbital φ is, within the GP mean-field, given by $E_{GP}(N) - E_{GP}(N - 1) = \mu_{GP}$. Analogously, we can compute the energy needed to remove a particle from the orbital φ_1 and that from the orbital φ_2 in the framework of the present mean-field. Using eqs.(3,4) and remembering that φ_1 and φ_2 are orthogonal, we readily find: $\mu_{11} = E(n_1, n_2) - E(n_1 - 1, n_2)$ and $\mu_{22} = E(n_1, n_2) - E(n_1, n_2 - 1)$. In other words, μ_{11} and μ_{22} can be viewed as *chemical potentials* of the $\{\varphi_1\}$ - and $\{\varphi_2\}$ -particle manifolds, respectively.

Another interesting property of (3,4) is that, unless $n_1 = n_2 = N/2$, these equations are not invariant to rotations (unitary transformations) of the pair (φ_1, φ_2) . This is due to the fact that φ_1 and φ_2 appear a different number of times in the wave function in contrast to the situation for identical fermions where the mean-field equations (Hartree-Fock) are indeed invariant to rotations [14]. As an important consequence the off-diagonal Lagrange parameters μ_{12} and μ_{21} can not, in general, be removed from eq.(4) by an unitary transformation. Finally we mention that $n_1 \mu_{12} = n_2 \mu_{21}$.

The factor $2\lambda_0 n_1 n_2$ appearing in the energy (3) and the corresponding term in (4) deserve attention. If the bosons residing in φ_1 would be distinguishable from those living in φ_2 , this factor will reduce to $\lambda_0 n_1 n_2$. The remaining factor $\lambda_0 n_1 n_2$ appears because of the *exchange* interaction between the two manifolds of identical bosons. Concentrating on many bosons, i.e. $n_1, n_2 \gg 1$, equations

(3,4) become more transparent. Then we may introduce the orbitals $\phi_1 = (n_1/N)^{1/2} \varphi_1$ and $\phi_2 = (n_2/N)^{1/2} \varphi_2$ which are, of course orthogonal, but now normalized to n_1/N and n_2/N , i.e., to the fraction of particles residing in φ_1 and φ_2 , respectively. The energy (3) can now be expressed as

$$\begin{aligned} E &= E_{cl} + E_{ex} \\ E_{cl} &= \bar{h}_{11} + \bar{h}_{22} + \frac{\lambda}{2} \int \rho^2(\vec{r}) d\vec{r} \\ E_{ex} &= \lambda \int |\phi_1|^2 |\phi_2|^2 d\vec{r} \end{aligned} \quad (5)$$

where $\bar{h}_{ii}$ is defined as h_{ii} in (3), but with the orbitals ϕ_i and

$$\rho = [n_1 |\varphi_1|^2 + n_2 |\varphi_2|^2] / N = |\phi_1|^2 + |\phi_2|^2$$

is the density per particle. It is easy to see that the 'classical' energy E_{cl} is invariant to unitary transformation of the pair (ϕ_1, ϕ_2) while the exchange energy E_{ex} is not. It is the latter energy which makes the situation interesting. Without the exchange energy also the equations for the optimal orbitals, eq.(4), would be invariant to unitary transformations.

In the following we demonstrate that the mean-field energy (3) can be superior to the GP energy (1). Our example consists of an one-dimensional attractive condensate ($\lambda_0 < 0$) in an external symmetric double-well potential. We choose as potential ($a \geq |x_0|$)

$$V(x) = c + \frac{1}{2} \omega x^2 - \omega a [x^2 - x_0^2 + a^2]^{1/2} \quad (6)$$

where the bottoms of the well are at $x = \pm x_0$. The parameter a is chosen such that $V(\pm x_0) = 0$. The corresponding kinetic energy reads $\hat{T} = -\frac{\omega}{2} \frac{\partial^2}{\partial x^2}$ implying that x is a dimensionless coordinate. Since the potential is symmetric, the ground state of h is a gerade function and the first excited state is an ungerade function of x . We, therefore, consider in our mean-field φ_1 and φ_2 to be gerade and ungerade functions of x , respectively. As can be seen from eq.(4) one finds $\mu_{12} = \mu_{21} = 0$ because φ_1 and φ_2 possess different spatial symmetries. The equations for the optimal orbitals have been evaluated numerically, by solving the resulting eigenvalue equations self-consistently using DVR [15] and finite-difference [16] methods. Both methods have led to identical results.

Using the same numerical procedures we have also solved the GP equation (2) and determined φ . Having found the optimal orbitals, we have computed the mean-field energies E and E_{GP} . Figure 1 shows the difference of the energies per particle $(E - E_{GP})/N$ as a function of the fractional occupation n_1/N for several values of the coupling constant $\lambda = \lambda_0 N$ (note that $N \gg 1$). At $n_1/N = 1$ the energy E , of course, coincides with the GP energy E_{GP} for all

values of λ . For $\lambda = 0.5$ the energy E grows as n_1/N is decreased. This is also true for $\lambda = -0.5$, but the growth of E is less pronounced. Until about $\lambda \approx -1.0$, $E > E_{GP}$ implying that the GP mean field is the best mean field and no particle occupy φ_2 . At $\lambda \leq -1.0$ the scenario changes as the energy E drops below E_{GP} as a function of the fractional occupation n_1/N for a given value of λ . The optimal mean field is obtained at the minimum of the curve $E = E(n_1/N)$. This minimum is about $n_1/N = 3/4$ for $\lambda = -1.5$ and approaches $n_1/N = 1/2$ continuously as λ is further decreased to $\lambda = -4.0$. The energy gain per particle due to the present mean field is substantial; for the same potential the energy difference between the ground and first excited states of $h = T + V$ is ~ 0.18 and the height of the barrier separating the two wells is ~ 1.0 .

The results are better understood by inspecting fig.2 which shows the density per particle $\rho(x)$ for $\lambda = -2.5$ and $n_1/N = 0.6$. As can be seen in fig.1, this value of n_1/N corresponds to the minimum of the energy for $\lambda = -2.5$. The GP density per particle $|\varphi(x)|^2$ is also shown in fig.2 for comparison. It is eye catching that much of $|\varphi(x)|^2$ has moved from the center of the potential $x \approx 0.0$ to its wells as an impact of the present mean field. Furthermore, the two peaks of the density have narrowed. The density $\rho(x)$ has substantially localized in comparison to the GP density. Since the condensate is attractive ($\lambda < 0$), localization is well-known to lead to a lowering of the energy [10]. What is surprising is that localization beyond the symmetry preserved GP density can be achieved in the framework of a mean-field approach without breaking the symmetry and without the necessity to go beyond the mean-field world. We remark that the system should have more than two bosons to achieve this localization: because of the different spatial symmetries of φ_1 and φ_2 , their product is not gerade as the ground state is expected to be. If more bosons are present, an even number of them can reside in φ_2 .

The energy E has been discussed above as a function of n_1 . The particle occupation n_1 is a variational parameter and we may ask whether the minimum of $E = E(n_1)$ can be determined directly without computing first the energy as a function of n_1 and subsequently searching for the minimum. The answer is positive. We define a new function

$$\tau(n_1, n_2) = E(n_1, n_2) + \nu(n_1 + n_2 - N) \quad (7)$$

of n_1 and n_2 and the constraint $n_1 + n_2 = N$ is represented by the Lagrange parameter ν . At its extrema $\partial\tau/\partial n_1 = \partial\tau/\partial n_2 = 0$, leading to two relations, one of which fixes ν and other gives rise to the equality $\partial E/\partial n_1 = \partial E/\partial n_2$. Taking the derivative of E in (3) with respect to n_1 and n_2 for $n_1, n_2 \gg 1$ recovers the expressions for μ_{11} and μ_{22} determined from (4), i.e., $\mu_{ii} = \partial E/\partial n_i, i = 1, 2$. Consequently we find that the two quantities μ_{11} and μ_{22} are

equal at the extremum of E :

$$\mu_{11} = \mu_{22} \equiv \mu \quad (8)$$

This is a relevant finding for understanding the concept of a condensate and, furthermore, allows us to transform the basic eqs.(4) at the optimal occupation n_1 as discussed in the following.

We now introduce the new orbitals

$$\begin{aligned} \psi_1(\vec{r}) &= \left(\frac{n_1}{N}\right)^{1/2} \varphi_1(\vec{r}) + \left(\frac{n_2}{N}\right)^{1/2} \varphi_2(\vec{r}) \\ \psi_2(\vec{r}) &= \left(\frac{n_2}{N}\right)^{1/2} \varphi_2(\vec{r}) - \left(\frac{n_1}{N}\right)^{1/2} \varphi_1(\vec{r}) \end{aligned} \quad (9)$$

and express (4) by them. Confining ourselves to the minimum of E and using the basic relation (8), the resulting equations for ψ_1 and ψ_2 simplify considerably:

$$\begin{aligned} \{ h(\vec{r}) + \frac{3}{4}\lambda|\psi_1|^2 + \frac{1}{4}\lambda|\psi_2|^2 \} \psi_1 &= (\mu + \bar{\mu}) \psi_1 \\ \{ h(\vec{r}) + \frac{3}{4}\lambda|\psi_2|^2 + \frac{1}{4}\lambda|\psi_1|^2 \} \psi_2 &= (\mu - \bar{\mu}) \psi_2. \end{aligned} \quad (10)$$

The equations (4) for the orbitals φ_1 and φ_2 are, in general, not eigenvalue equations. The corresponding equations for ψ_1 and ψ_2 at the optimum occupation n_1 are eigenvalue equations. The eigenvalues are $(\mu + \bar{\mu})$ and $(\mu - \bar{\mu})$, where μ is the condensate's chemical potential (see (8)) and $\bar{\mu} \equiv (n_1/n_2)^{1/2} \mu_{12} = (n_2/n_1)^{1/2} \mu_{21}$.

At first sight it is intriguing to see that the new eqs.(10) do not exhibit the optimal n_1 and n_2 . Nevertheless, these occupations can be deduced from these equations. To this end it is relevant to notice that (9) is not a unitary transformation. Indeed, ψ_1 and ψ_2 are normalized to unity, $\langle \psi_1 | \psi_1 \rangle = \langle \psi_2 | \psi_2 \rangle = 1$, but they are *not* orthogonal. Their scalar product is

$$\langle \psi_1 | \psi_2 \rangle = \frac{n_2 - n_1}{N} \quad (11)$$

and determines the optimal occupations. One can solve the two eigenvalue equations (10) self-consistently and compute the optimal n_1 and n_2 from the final result. We have tested this procedure for several numerical examples including the above discussed double-well case. One directly obtains the minima

of the energy curves shown in fig.1. A practical hint: numerical stability is enhanced if at each iteration step use is made of the relationship (9) between ψ_1 and ψ_2 .

Let us conclude. By expressing the wave functions as a symmetrized product of single-particle functions (orbitals), equations for the mean-field energy and the optimal orbitals are derived. Several bosons can reside in each of these orbitals φ_i and it is a basic property of the present approach that these occupation numbers n_i are variational parameters which can be used to minimize the energy. An explicit numerical example is presented demonstrating that the mean-field energy using two orbitals can be lower than the GP energy. Since in the absence of interaction between the particles, all particles reside in a single orbital to form the ground state of the condensate, it is clear that the present approach reproduces the GP result for weak interactions. Beyond some critical interaction strength $\lambda = \lambda_0 N$ obtained, for instance, by increasing the number N of particles in the condensate, the mean-field energy can drop below the GP one. This critical value depends strongly on the external potential. By varying the shape and parameters of this potential one can lower or raise the interesting range of λ substantially.

In our simple example it has been shown that the mean-field energy can drop below the GP energy for a continuous range of the occupation n_i . The system then consists of two (or more) subsystems each possessing its own chemical potential. This may contradict the picture one usually has of a condensate. It is, therefore, very interesting to note that these, in general different, chemical potentials become identical at the optimal occupations n_i which minimize the energy $E(\{n_i\})$ restoring thereby the picture of a condensate. This finding leads to another highlight of this work: self-consistent eigenvalue equations for the optimal orbitals at the optimal occupations could be derived.

It should be kept in mind that the occupation numbers n_i are variational parameters in the present mean-field and, therefore, the solution of eq.(10) will tell us via eq.(11) which the optimal occupation numbers are. In those cases where one finds that $n_1/N = 1$, then all bosons reside in a single orbital, our ansatz reproduces the GP result and the GP mean field is thus the best mean field. The GP mean field is an excellent ansatz reflecting our physical expectation that in the ground state all bosons would like to occupy the same orbital in order to minimize the energy. It is, therefore, surprising that there exist counter examples at all. Here, we have shown that an attractive condensate in an one-dimensional symmetric double-well potential provides such a counter example. This finding is not restricted to the *specific shape* of the external symmetric double-well potential used here. Other counter examples can be expected. For instance, an attractive condensate in an one-dimensional symmetric multi-well potential. Here, however, as many orbitals must be included in the mean-field ansatz as there are wells. That macroscopic condensation can

be described by one-dimensional equations has been discussed in the literature, see, e.g. [10] and references therein. Clearly, it would be very interesting to study condensates in higher dimensions. Of course, the same equations as derived here hold also in this case, but their full numerical evaluation is more involved and such a study is left to the future. We note that in the present numerical example it is the symmetry of the problem which fails the GP mean field. In other examples the reason that GP is not the best mean field may be of different origin. We suspect, however, that if one finds n_1/N to deviate from 1, it is a helpful warning that one might have to go beyond the mean-field approach as such in order to describe the underlying physics properly.

Being non-linear equations, eqs. (4) and (10) may have several solutions. We have encountered examples where the lowest-energy solution is characterized by $n_1/N = 1$, but other low-lying solutions exist with n_1/N deviating from 1. The first solution, of course, corresponds to the system's ground state. In the latter solutions the bosons reside in two orbitals and their existence could be an indication for collective excited *self-consistent* states of the condensate. We remind that according to eq. (8) there exists only a single value of the chemical potential for each of these excited states making them attractive to further investigations.

Finally, we would like to mention very briefly that (a) time-dependent mean-field equations corresponding to the stationary equations discussed here are straightforwardly derived, and (b) the present mean-field equations provide an excellent starting point of investigating condensates beyond the mean-field approach.

Helpful discussions with Dieter Meyer and Ofir Alon are gratefully acknowledged.

Fig. 1. The difference between the present mean-field energy per particle $E(n_1)/N$ and the GP energy per particle E_{GP}/N is shown for several values of $\lambda = \lambda_0 N$ as a function of the fractional occupation n_1/N . It is seen that the energy $E(n_1)$ may drop substantially below the GP energy. At $n_1/N = 1$ both energies, of course, coincide. The external potential (4) has been used with $x_0 = 1.5$ and $a = 1.5015$. λ and the energies are given in units of ω

Fig. 2. The density per particle $\rho = (n_1|\varphi_1|^2 + n_2|\varphi_2|^2)/N$ is shown for one of the examples of fig.1 ($\lambda = -2.5$ and $n_1/N = 0.6$) and compared with the corresponding GP density per particle $\rho_{GP} = |\varphi|^2$.
